Abstract

22 Visual illusions are a gateway to understand how we construct our experience of reality.
23 Unfortunately, important questions remain open, such as the hypothesis of a common
24 factor underlying the sensitivity to different types of illusions, as well as of personality
25 correlates of illusion sensitivity. In this study, we used a novel parametric framework for
26 visual illusions to generate 10 different classic illusions (Delboeuf, Ebbinghaus, Rod and
27 Frame, Vertical-Horizontal, Zöllner, White, Müller-Lyer, Ponzo, Poggendorff, Contrast)
28 varying in strength, embedded in a perceptual discrimination task. We tested the objective
29 effect of the illusions on errors and response times, and extracted participant-level
30 performance scores ($n=250$) for each illusion. Our results provide evidence in favour of a
31 general factor underlying the sensitivity to different illusions (labelled Factor i). Moreover,
32 we report a positive link between illusion sensitivity and personality traits such as
33 Agreeableness, Honesty-Humility, and negative relationships with Psychoticism,
34 Antagonism, Disinhibition, and Negative Affect.

37 A Novel Visual Illusion Paradigm Provides Evidence for a General Factor of
38 Illusion Sensitivity and Personality Correlates

39 Significance Statement. A novel paradigm to study the objective effect of visual
40 illusions yielded evidence in favor of a common factor to visual illusions (Factor *i*) and a
41 relationship between illusion resistance and maladaptive personality traits, such as
42 antagonism, psychoticism and disinhibition.

Introduction

44 Visual illusions are fascinating stimuli capturing a key feature of our neurocognitive
45 systems. They eloquently show that our brains did not evolve to be perfect perceptual
46 devices providing veridical accounts of physical reality, but integrate prior knowledge and
47 contextual information - blended together in our subjective conscious experience¹. Despite
48 the long-standing interest within the fields of visual perception²⁻⁴, consciousness science^{5,6},
49 and psychiatry⁷⁻¹⁰, several important issues remain open.

50 One area of contention concerns the presence of a common mechanism underlying the
51 effect of different illusions^{11,12}. While early research has suggested a common factor of
52 illusion sensitivity indexed by overall vision proficiency^{13,14}, recent empirical studies
53 observed at most weak correlations between inter-individual resistance to distinct
54 illusions^{15,16}. The existence of dispositional correlates of illusion sensitivity has also been
55 controversial, with evidence suggesting a lower illusion sensitivity in patients with
56 schizophrenia and autism^{7-9,16,17}, as well as individuals with stronger aggression and
57 narcissism traits^{18,19}.

58 Although the nature of the processes underlying illusion perception - whether related
59 to low-level features of the visual processing system^{8,20} or to top-down influences^{5,21} -
60 remains debated, a growing body of literature proposes to conceptualize illusions under the
61 Bayesian brain hypothesis²². In this context, illusions are conceptualized as **non-veridical**

62 **perceptual experiences that result from giving ample weight to prior knowledge**
63 **to minimize prediction error in the face of biasing sensory evidence.** The
64 predictive coding account further provides an explanation regarding the observations from
65 clinical populations. Certain dispositional traits or characteristics (e.g., psychoticism) are
66 seen as driven by alterations in the system's metacognitive components²³, resulting in an
67 underweighting of priors during perceptual inferences, and manifesting as a decreased
68 sensitivity to illusions²⁴.

69 Despite strong theoretical foundations and hypotheses, the empirical evidence remains
70 scarce, clouded by methodological hurdles. For instance, one key challenge can be found in
71 the difficulty of adapting visual illusions to an experimental setting, which typically
72 requires the controlled modulation of the specific variables of interest. Instead, existing
73 studies typically use only one or a small subset of illusion types, with few contrasting
74 conditions, restricting the findings' generalizability^{12,20,25}. Moreover, conventional
75 paradigms often focus on the participants' subjective experience, by asking them the extent
76 to which they perceive two identical targets as different²⁶, having them estimate the
77 targets' physical properties²⁷, **or through the method of adjustment, which involves**
78 **having them adjust the targets to perceptually match a reference**
79 **stimulus**^{16,28–30}. This reliance on meta-cognitive judgements about one's subjective
80 experience likely distorts the measurand, limiting the ability to reliably obtain more direct
81 and objective measures of illusion sensitivity³¹. **While some recent efforts have some**
82 **made to implement more empirically rigorous paradigms**³², **most of the applied**
83 **manipulations only focus on varying the physical dimensions of the illusion's**
84 **target features without modulating its contextual elements, hence limiting the**
85 **variability in the illusory effects of the stimuli presented.** Furthermore, such
86 **prior studies have typically generated stimuli whose targets' physical attributes**
87 **vary over a relatively narrow range, thus further constraining the reliability of**
88 **their findings.** As such, it is possible that the recent evidence reported against

89 a common factor of illusions could be due to the low stimulus variance instead
90 of a true reflection of a lack of common mechanism.

91 To address these issues, we first developed a parametric framework to manipulate
92 visual illusions that we implemented and made accessible in the open-source software
93 *Pyllusion*³³. This software allows us to generate different types of classic visual illusions
94 with a continuous and independent modulation of two parameters: *illusion strength* and
95 *task difficulty* (**Figure 1**). Indeed, many visual illusions can be seen as being composed of
96 *targets* (e.g., same-length lines), of which perception is biased by the *context* (e.g., in the
97 Müller-Lyer illusion, the same-length line segments appear to have different lengths if they
98 end with inwards vs. outwards pointing arrows). Past illusion studies traditionally
99 employed paradigms focusing on participants' subjective experience, by asking them the
100 extent to which they perceive two identical targets as different²⁶, or having them adjust the
101 targets to match a reference stimulus relying only on their perception^{16,28}. Alternatively,
102 *Pyllusion* allows the creation of illusions in which the targets are objectively different (e.g.,
103 one segment is truly more or less longer than the other), and in which the illusion varies in
104 strength (the biasing angle of the arrows is more or less acute).

105 This systematic calibration of the stimuli enables the creation of experimental tasks
106 in which participants make perceptual judgments about the targets (e.g., which segment is
107 the longest) under different conditions of objective difficulty and illusion strength.
108 Moreover, the illusion effect can be specified as either “incongruent” (making the task more
109 difficult by biasing the perception in the opposite way) or “congruent” (making the task
110 easier). Although visual illusions are inherently tied to subjective perception, this
111 framework allows a reversal of the traditional paradigm to potentially quantify the
112 “objective” effect of illusions by measuring its behavioral effect (error rate and reaction
113 times) on the performance in a perceptual task.

114 The aim of the present preregistered (<https://osf.io/5d6xp>) study is three-fold. First,

Parametric Framework for Visual Illusions

Example with the Müller-Lyer Illusion

The Müller-Lyer Illusion is traditionally presented as two segments (the **red targets**), which perception is biased by the **context** (the arrows). Here, the lower segment appears longer despite being of the same length.

In this illusion, the **task difficulty** corresponds to the difference between the lengths of the red target segments, and the **illusion strength** corresponds to the angle of the arrows. The **illusion direction** corresponds to the facilitating or impeding effect with regards to the task at hand.

Example of Stimuli

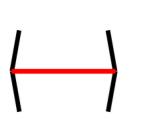

❖ Task difficulty: **easy**
(top line is 2 times longer)

❖ Illusion Strength: **strong**
(angle is sharp)

❖ Illusion Direction: **incongruent**
(the illusion makes the task harder: red lines look more similar)

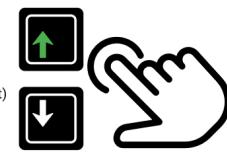

❖ Task difficulty: **hard**
(top line is only 1.1 times longer)

❖ Illusion Strength: **weak**
(angle is flat)

❖ Illusion Direction: **congruent**
(the illusion makes the task easier: red lines look more different)

Task: For these stimuli, the correct response is always the « up » arrow, indicating the longer red segment. We measured the reaction time and the errors (in this case, the « down » arrow).

Stimuli created with the open-source software PyMusion (Makowski et al., 2021)

Figure 1. The parametric framework for visual illusions (Makowski et al., 2021) applied to the Müller-Lyer illusion (above). Below are examples of stimuli showcasing the manipulation of two parameters, task difficulty and illusion strength.

we will test this novel paradigm by investigating if the effect of illusion strength and task difficulty can be manipulated continuously for 10 different classic illusions (Delboeuf, Ebbinghaus, Rod and Frame, Vertical-Horizontal, Zöllner, White, Müller-Lyer, Ponzo, Poggendorff, Simultaneous Brightness Contrast). Next, we will investigate the factor structure of illusion-specific performance scores and test the existence of a common latent factor of illusion sensitivity. Finally, we will explore how illusion sensitivity relates to demographic characteristics, contextual variables, and personality traits.

122

Methods

123 **Ethics Statement**

124 This study was approved by the NTU Institutional Review Board (NTU
125 IRB-2022-187) and all procedures performed were in accordance with the ethical standards
126 of the institutional board and with the 1964 Helsinki Declaration. All participants
127 provided their informed consent prior to participation and were incentivized after
128 completing the study.

129 **Stimuli**

130 We investigated the effect of 10 different classic illusions (**Figure 2**). A pilot study (n
131 = 46), of which a full description is available at
132 <https://github.com/RealityBending/IllusionGameValidation>, was first conducted
133 to determine a sensitive range of stimuli parameters. Then, for each of the 10 illusion
134 types, we generated a total of 134 stimuli. These stimuli resulted from the combination of
135 15 equally-spaced levels of illusion *strength* (7 negative, i.e., congruent effects; 7 positive,
136 i.e., incongruent effects) overlapped with 16 non-linearly spaced task *difficulty* levels (i.e.,
137 with an exponential, square or cubic spacing depending on the pilot results). For instance,
138 a linear space of [0.1, 0.4, 0.7, 1.0] can be transformed to an exponential space of [0.1, 0.34,
139 0.64, 1.0], where 0.1 corresponds to the highest difficulty - i.e., the smallest objective

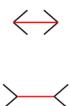

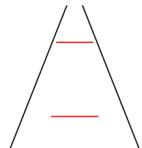

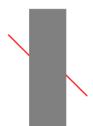

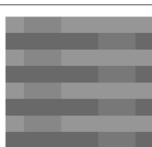

Illusion	Example	Task	Description
Delboeuf		Which red circle is bigger? 	Two circles surrounded by outer rings. The circle with the closer outline appears larger than the one with the distant outline.
Ebbinghaus		Which red circle is bigger? 	Two circles surrounded by other circles. The circle surrounded by smaller circles appears larger than the one with the larger surrounding circles.
Müller-Lyer		Which red line is longer? 	Two parallel segments that end with inwards/outwards pointing arrow-like fins. The segment with inward-pointing fins is typically perceived to be longer.
Ponzo Illusion		Which red line is longer? 	Two parallel segments embedded between a pair of converging lines. The segment on the convergence side is typically perceived to be longer.
Vertical-Horizontal		Which red line is longer? 	Two line segments, one horizontal and one angled. The angled line is usually perceived as longer.
Zöllner		Which direction are the red lines converging towards? 	Represented by two long lines crossed with short, repeated lines, that appear as converging to one side.
Rod and Frame		Which direction is the red line leaning towards? 	A segment ("rod") enclosed in a tilted square ("frame"), that appears to be leaning to one side.
Poggendorff		Is the right line above or below the left line? 	Two oblique segments separated by a rectangle. The right segment appears to be vertically misplaced.
Simultaneous Contrast		Which small rectangle is lighter? 	Consists of two smaller grey rectangles embedded in backgrounds of different contrasts. The rectangle with the darker background appears lighter.
White		Which vertical rectangle is lighter? 	Composed of a series of contrasting horizontal bars superimposed with vertical grey rectangles. Rectangles superimposed onto darker bars appear lighter.

Figure 2. Ten different illusions were used as stimuli in a perceptual task, where participants had to answer as fast as possibly, without making errors, according to specific instructions. For each illusion type, two parameters were experimentally manipulated, 1) the task difficulty (e.g., how large was the difference between the bigger and the smaller red circles in the Delboeuf illusion), and 2) the illusion strength (e.g., the size of the black circles in the Ebbinghaus illusion).

¹⁴⁰ difference between targets). For each illusion type, the stimuli were split into two series (56
¹⁴¹ and 72 stimuli per series) with alternating parameter values to maintain their homogeneity.
¹⁴² Additionally, 6 stimuli per illusion type were generated for a practice series using
¹⁴³ parameters with more extreme variations (i.e., containing very easy trials to help cement
¹⁴⁴ the task instructions).

¹⁴⁵ Procedure

¹⁴⁶ Participants were first given a brief demographic survey, which collected information
¹⁴⁷ regarding their **age, gender, country of birth, ethnicity and highest attained**
¹⁴⁸ **education level**. This was followed by a practice series of illusions, after which the first
¹⁴⁹ series of 10 illusion blocks was presented in a randomized order, with a further
¹⁵⁰ randomization of the stimuli order within each block. Following this first series of blocks,
¹⁵¹ two personality questionnaires were administered, the *IPIP6*³⁴ - measuring 6 “normal”
¹⁵² personality traits (Extraversion, Openness, Conscientiousness, Agreeableness, Neuroticism
¹⁵³ and Honesty-Humility), and the *PID-5*³⁵ - measuring 5 “pathological” personality traits
¹⁵⁴ (Disinhibition, Antagonism, Detachment, Negative Affect and Psychoticism). Next, the
¹⁵⁵ second series of 10 illusion blocks was presented (with new randomized orders of blocks and
¹⁵⁶ trials). In total, each participant underwent 1340 trials of which they had to respond “as
¹⁵⁷ fast as possible without making errors” (i.e., an explicit double constraint to mitigate the
¹⁵⁸ inter-individual variability in the speed-accuracy trade off) by pressing the correct arrow
¹⁵⁹ key (left/right, or up/down depending on the illusion type). For instance, in the
¹⁶⁰ Müller-Lyer block, participants had to answer which one of the upper or bottom target line
¹⁶¹ was the longest. **All trials were required to be completed within a single-session**
¹⁶² **(total experiment duration: ~55 minutes)**. The task was implemented using
¹⁶³ *jsPsych*³⁶ and was hosted on *Pavlovia* (<https://pavlovia.org/>). The set of
¹⁶⁴ instructions for each illusion type is available in the experiment code.

165 **Participants**

166 Participants were recruited via *Prolific*, a crowd-sourcing platform recognized for
167 providing high quality data³⁷. The only inclusion criterion was a fluent proficiency in
168 English to ensure that the task instructions would be well-understood. Participants were
169 incentivised with a reward of about £7.50 for completing the task, which took
170 approximately 50 minutes to finish. Demographic variables (age, gender, and ethnicity)
171 were self-reported on a voluntary basis.

172 We excluded 6 participants upon inspection of the average error rate (when close to
173 50%, suggesting random answers), and reaction time distribution (when implausibly fast
174 relative to the average RT distribution). For the remaining participants, we discarded
175 blocks with more than 50% of errors (2.16% of trials), possibly indicating that instructions
176 were misunderstood (e.g., participants focused on the shorter line instead of the longer
177 one), and 0.76% trials with extreme response times (< 125 ms or > 4 SD above mean RT).
178 Additionally, due to a technical issue, no personality data was recorded for the first eight
179 participants.

180 The final sample included 250 participants (Mean age = 26.5, SD = 7.6, range: [18 -
181 69]; Sex: 48% females, 52% males).

182 **Data Analysis**

183 The first part of the analysis focused on modelling the effect of illusion strength and
184 task difficulty on errors and response time (RT) **separately for each illusion** under a
185 Bayesian framework. We started by fitting General Additive Models (GAMs), which can
186 parsimoniously accommodate possible non-linear effects and interactions. Errors were
187 analyzed using logistic mixed models (**suites to estimate the error rate**), and RTs of
188 correct responses were analyzed using an ex-Gaussian family with the same fixed effects
189 entered for the location μ (mean), scale σ (spread) and tail-dominance τ of the RT

190 distribution^{38,39}.

191 Using GAMs as the “ground-truth” models, we attempted at approximating them
192 using general linear mixed models, which can be used to estimate the effects’
193 participant-level variability (via random slopes). Following a comparison of models with a
194 combination of transformations (raw, log, square root or cubic root; **which are types of**
195 **relationship commonly found in perceptual tasks**) on the main predictors (task
196 *difficulty* and illusion *strength*), we fitted the best model (**based on their BIC and R2**),
197 and compared their output visually (**Figure 3**). Note that the model comparison and
198 the parameters used in the resulting models were not pre-registered.

199 The inter-individual variability in the effect of illusion strength and its interaction
200 with task difficulty (**diff**) was extracted from the models and used as participant-level
201 scores. We then explored the relationship of these indices across different illusions using
202 exploratory factor analysis (**EFA, to gain insights into the structure**), and structural
203 equation modelling (**SEM, to model and test different hierarchical models**), and
204 tested the existence of a general factor of illusion sensitivity (Factor *i*).

205 Finally, for each of the individual illusion sensitivity scores (10 illusion-specific factors
206 and the general Factor *i*), we tested the effect of contextual variables (screen size, screen
207 refresh rate), demographic variables (sex, education, age), and personality traits. It should
208 be noted that the measure of screen size used (measured using the number of pixels) is
209 **only a proxy of the true physical screen size**.

210 The analysis was carried out using *R* 4.2⁴⁰, *brms*⁴¹, the *tidyverse*⁴², and the *easystats*
211 collection of packages^{43–46}. As all the full results have been made available (see **Data**
212 **Availability**), we will focus here on the significant results (based on the Bayes Factor *BF*
213 or the Probability of Direction *pd*⁴⁷).

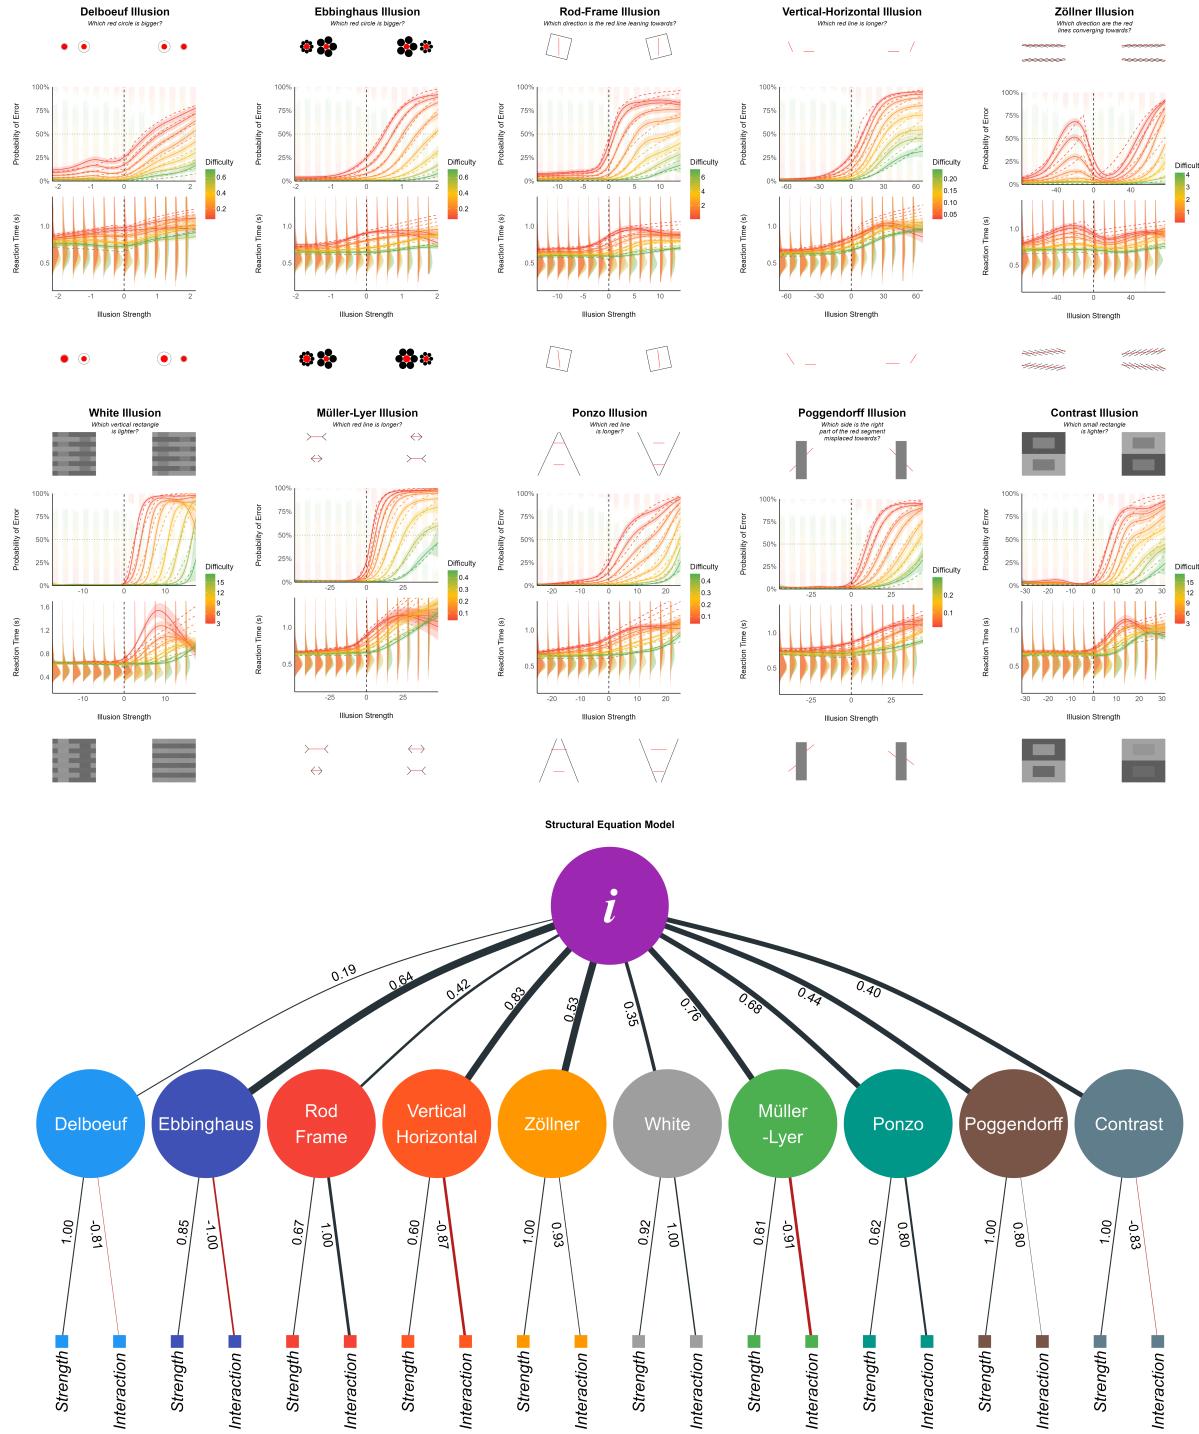

Figure 3. Top: the effect of illusion strength and task difficulty on the error rate and reaction time (RT) for each individual illusion. The solid line represents the General Additive Model (GAM), and the dashed line corresponds to its approximation via linear models. Descriptive data is shown with stacked dots (for which errors start from the top) and distributions for RTs. Negative values for illusion strength correspond to congruent (i.e., facilitating) illusion effects. Task difficulty (the objective difference between the targets of perceptual decision) levels are shown as colors, with lower values corresponding to harder trials. The results for each illusion are surrounded by 4 extreme examples of stimuli, corresponding to lowest to the hardest difficulty (bottom to top) and the weakest to strongest illusion (from left to right for incongruent illusions). Bottom: We extracted the effect slope of the illusion strength and its interaction with task difficulty for each participant. We fitted a Structural Equation Model (SEM) suggesting that these manifest variables group to first-level illusion-specific latent factors, which then load on a general factor of illusion sensitivity (Factor i).

214

Results

215 **Effects of Illusion Strength and Task Difficulty**

216 The best model specifications were $\log(\text{diff}) * \text{strength}$ for Delboeuf;
217 $\sqrt{\text{diff}} * \text{strength}$ for Ebbinghaus; $\log(\text{diff}) * \log(\text{strength})$ for Rod and Frame;
218 $\sqrt{\text{diff}} * \sqrt{\text{strength}}$ for Vertical-Horizontal; $\text{cbrt}(\text{diff}) * \text{strength}$ for Zöllner;
219 $\text{diff} * \sqrt{\text{strength}}$ and $\log(\text{diff}) * \text{strength}$ respectively for errors and RT in White;
220 $\sqrt{\text{diff}} * \sqrt{\text{strength}}$ and $\sqrt{\text{diff}} * \text{strength}$ respectively for errors and RT in
221 Müller-Lyer; $\text{cbrt}(\text{diff}) * \text{strength}$ for Ponzo; $\text{cbrt}(\text{diff}) * \sqrt{\text{strength}}$ and
222 $\text{cbrt}(\text{diff}) * \text{strength}$ respectively for errors and RT in Poggendorff; and
223 $\sqrt{\text{diff}} * \sqrt{\text{strength}}$ for Contrast. For all of these models, the effects of illusion
224 strength, task difficulty and their interaction were significant.

225 For error rates, most of the models closely matched their GAMs counterpart, with
226 the exception of Delboeuf (for which the GAM suggested a non-monotonic effect of illusion
227 strength with a local minimum at 0) and Zöllner (for which theoretically congruent illusion
228 effects were related to increased error rate). A specific discussion regarding these 2 illusions
229 is available in the study documentation (part 1) at
230 <https://github.com/RealityBending/IllusionGameValidation>.

231 For RTs, the GAMs suggested a consistent non-linear relationship between RT and
232 illusion strength: as the illusion strength increases beyond a certain threshold, the
233 participants responded faster. While this is not surprising (strong illusions are likely so
234 effective in biasing perception that it is “easier”, i.e., faster, to make the wrong decision),
235 the linear models were not designed to capture this - likely quadratic - pattern and hence
236 are not good representatives of the underlying dynamics. As such, we decided not to use
237 them for the individual scores analysis.

238 Factor Structure

239 Though imperfect, we believe that the random-slope models capture inter-individual
240 differences with more accuracy (and also provide more conservative estimates due to
241 shrinkage) than basic empirical scores, such as the total number of errors, or the average
242 RT. Thus, for each illusion and within each participant, we extracted the effect of illusion
243 strength and its interaction with task difficulty when the illusion effect was incongruent.
244 These twenty participant-level scores were subjected to exploratory factor analysis (EFA).
245 The Method Agreement Procedure⁴⁸ suggested the presence of 7 latent factors. An oblique
246 (*oblimin* rotation) factor solution explaining 66.69% of variance suggested separate
247 dimensions for the effect of Zöllner, White, Poggendorff, Contrast, Ebbinghaus, Delboeuf,
248 and a common factor for the parameters related to Müller-Lyer, Vertical-Horizontal, Ponzo
249 and Rod and Frame. We submitted these factors to a second-level analysis and extracted
250 two orthogonal (*varimax* rotation) factors. The first factor was loaded by all the previous
251 dimensions with the exception of Delboeuf, which formed its own separate factor.

252 Finally, we tested this data-driven model (*m0*) against four other structural models
253 using structural equation modelling (SEM): one in which the two parameters of each of the
254 10 illusions (illusion strength and interaction with task difficulty) loaded on separate
255 factors, which then all loaded on a common factor (*m1*); one in which the parameters were
256 grouped by illusion type (lines, circles, contrast and angle) before loading on a common
257 factor (*m2*); one in which all the parameters related to strength, and all the parameters
258 related to the interaction loaded onto two respective factors, which then loaded on a
259 common factor (*m3*); and one in which there was no intermediate level: all 20 parameters
260 loaded directly on a common factor (*m4*).

261 The model *m1*, in which the parameters loaded on a first level of 10 illusion-specific
262 factors, which then all loaded on a common factor, significantly outperformed the other
263 models. Its indices of fit ranged from acceptable to satisfactory (CFI = .92; SRMR = .08;

264 NNFI = .91; PNFI = .74; RMSEA = .08), and all the specified effects were significant.
265 The illusion-specific latent factors were loaded positively by the sensitivity to illusion
266 strength, as well as by the interaction effect with task difficulty (with the exception of
267 Delboeuf, Ebbinghaus, Vertical-Horizontal, Müller-Lyer and Contrast, for which the
268 loading was negative). The general factor of illusion sensitivity, labelled Factor i (i- for
269 illusion), explained 48.02% of the total variance of the initial dataset, and was strongly
270 related to Vertical-Horizontal ($\beta_{std.} = 0.83$), Müller-Lyer ($\beta_{std.} = 0.76$), Ponzo
271 ($\beta_{std.} = 0.65$), Ebbinghaus ($\beta_{std.} = 0.64$); moderately to Zöllner ($\beta_{std.} = 0.53$), Poggendorff
272 ($\beta_{std.} = 0.44$), Rod and Frame ($\beta_{std.} = 0.42$), Contrast ($\beta_{std.} = 0.40$) and White
273 ($\beta_{std.} = 0.35$); and weakly to Delboeuf ($\beta_{std.} = 0.19$). We then computed, for each
274 participant, the score for the 10 illusion-specific factors and for the general Factor i .

275 It is important to note that these individual scores are the result of several layers of
276 simplification: 1) the individual coefficient is that of simpler models that sometimes do not
277 perfectly capture the underlying dynamics (especially in the case of Delboeuf and Zöllner);
278 2) we only used the models on error rate, which could be biased by the speed-accuracy
279 decision criterion used by participants; 3) the structural equation model used to compute
280 the scores also incorporated multiple levels of abstractions. Thus, in order to validate the
281 individual scores, we computed the correlation between them and simple empirical scores,
282 such as the average error rate and the mean RT in the task. This analysis revealed strong
283 and significant correlations between each illusion-specific factor and the average amount of
284 errors in its corresponding task. Moreover, each individual score was strongly associated
285 with the average RT across multiple illusion types. This suggests that the individual scores
286 obtained from the structural equation model do capture the sensitivity of each participant
287 to visual illusions, manifesting in both the number of errors and long reaction times.

288 Correlations with Inter-individual Characteristics

289 The Bayesian correlation analysis (with narrow priors centered around a null effect)
290 between the illusion scores and contextual variables (screen size and refresh rate) provided
291 weak evidence in favor of an absence of effect, with the exception of the two contrast-based
292 illusions. Anecdotal ($BF_{10} = 2.05$) and moderate evidence ($BF_{10} = 4.11$) was found for a
293 negative correlation between screen size and the sensitivity to the White and the Contrast
294 illusion, respectively. To test whether this result could be an artifact related to the highly
295 skewed screen size distribution (caused by very few participants with extreme screen sizes),
296 we re-ran a robust correlation (with rank-transformed values), which provided even
297 stronger evidence in favor of the effect existence ($BF_{10} = 28.19$, $BF_{10} = 4.31$ for White and
298 Contrast, respectively).

299 The Bayesian t-tests on the effect of sex suggested anecdotal to moderate evidence in
300 favour of the null effect for all scores, with the exception of the sensitivity to the Zöllner
301 illusion, which was higher in males as compared to females ($\Delta = -0.37$, 95% CI [-0.62,
302 -0.13], $BF_{10} = 12.74$). We fitted Bayesian linear models with the education level entered as
303 a monotonic predictor (appropriate for ordinal variables^{49]}) which yielded no significant
304 effects. For age, we fitted two types of models for each score, one general additive models
305 (GAM) and a 2nd order polynomial model. These consistently suggested a significant
306 positive linear relationship between age and Factor i ($pd = 100\%$), as well as the sensitivity
307 to Müller-Lyer ($pd = 100\%$), Vertical-Horizontal ($pd = 100\%$), Zöllner ($pd = 100\%$) and
308 Ebbinghaus ($pd = 99\%$) illusions (**Figure 4**).

309 Regarding “normal” personality traits, Bayesian correlations suggested substantial
310 evidence in favor of a positive relationship between *Honesty-Humility* and Zöllner
311 ($BF_{10} > 100$), Vertical-Horizontal ($BF_{10} = 9.78$) and the Factor i ($BF_{10} = 4.00$); as well as
312 between *Agreeableness* and Vertical-Horizontal ($BF_{10} = 25.06$), Ponzo ($BF_{10} = 4.88$) and
313 the Factor i ($BF_{10} = 19.65$).

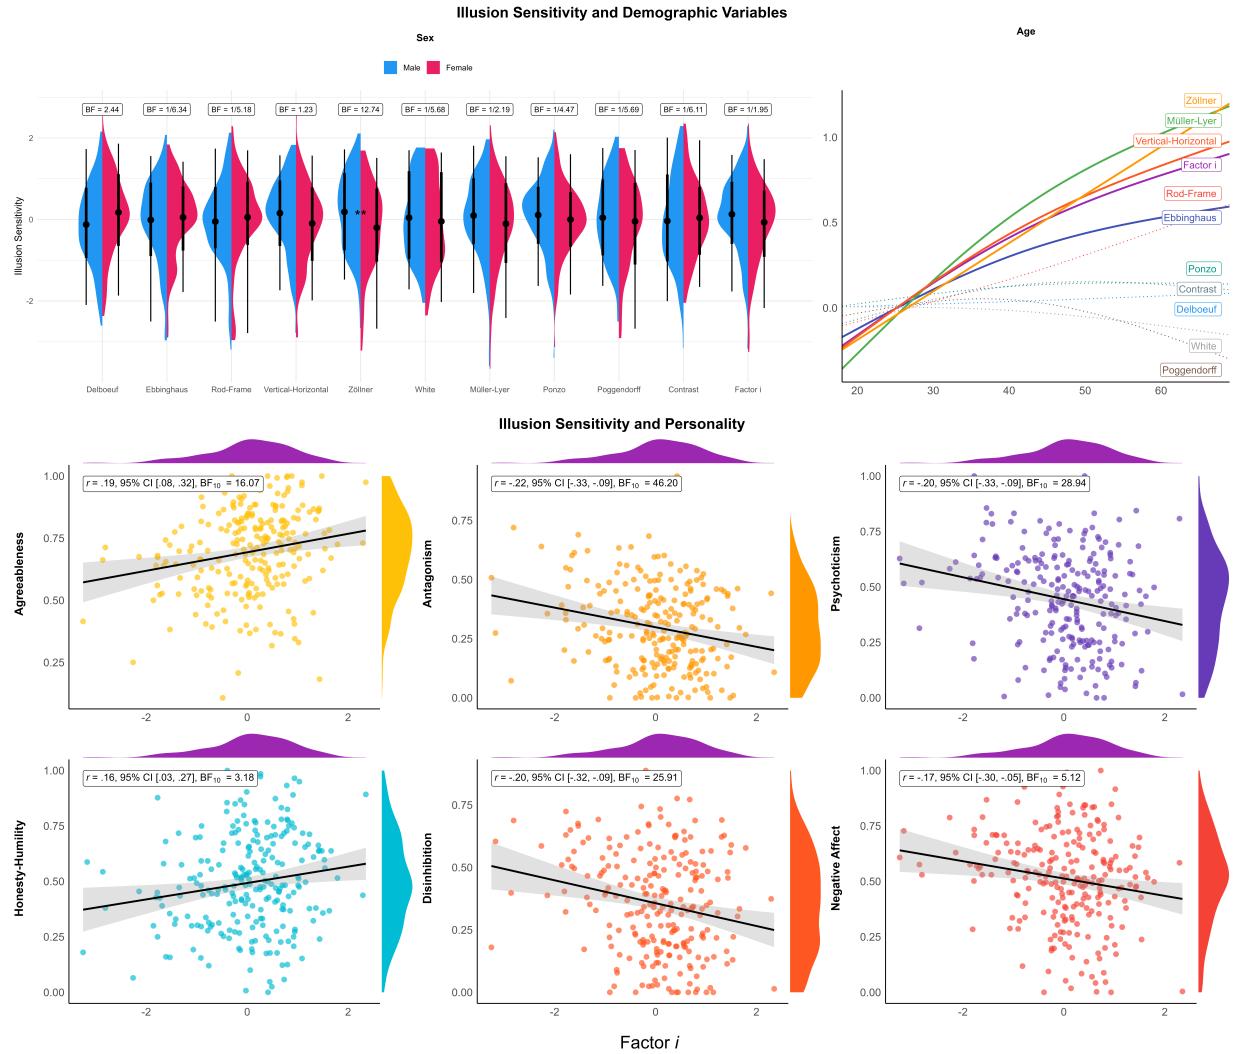

Figure 4. The upper plots show the illusion sensitivity scores as a function of sex and age (solid lines indicate significant relationships). Bottom plots show the correlation between the general factor (Factor *i*) of illusion sensitivity (on the x-axes) and personality traits.

314 Regarding “pathological” personality traits, the results yielded strong evidence in
315 favor of a negative relationship between illusion scores and multiple traits. *Antagonism* was
316 associated with the sensitivity to Vertical-Horizontal ($BF_{10} > 100$), Müller-Lyer
317 ($BF_{10} = 21.57$), Ponzo ($BF_{10} = 17.97$) illusions, and the Factor *i* ($BF_{10} = 55.45$);
318 *Psychoticism* was associated with the sensitivity to Vertical-Horizontal ($BF_{10} = 66.63$) and
319 Müller-Lyer ($BF_{10} = 35.59$) illusions, and the Factor *i* ($BF_{10} = 35.02$); *Disinhibition* was
320 associated with the sensitivity to Vertical-Horizontal ($BF_{10} = 25.38$), Zöllner
321 ($BF_{10} = 7.59$), Müller-Lyer ($BF_{10} = 5.89$) illusions, and the Factor *i* ($BF_{10} = 31.42$); and
322 *Negative Affect* was associated with Zöllner ($BF_{10} = 62.04$), Vertical-Horizontal
323 ($BF_{10} = 12.65$), Müller-Lyer ($BF_{10} = 3.17$), and the Factor *i* ($BF_{10} = 6.39$). The last
324 remaining trait, *Detachment*, did not share any significant relationship with illusion
325 sensitivity.

326

Discussion

327 This study tested a novel illusion sensitivity task paradigm based on the parametric
328 illusion generation framework³³. Using the carefully generated stimuli in a perceptual
329 decision task, we have shown that a gradual modulation of illusion strength is effectively
330 possible across 10 different types of classic visual illusions. Increasing the illusion strength
331 led to an increase in error likelihood, as well as the average and spread of RTs (but only up
332 to a point, after which participants become faster at responding with the wrong answer).
333 Using mixed models, we were able to statistically quantify the effect of illusions for each
334 illusion and each participant separately. This important methodological step opens the
335 door for new illusions-based paradigms and tasks to study the effect of illusions under
336 different conditions and to measure illusion sensitivity using objective behavioral outcomes
337 - such as accuracy or speed - instead of subjective meta-cognitive reports. This new and
338 complementary approach will hopefully help address some of the longstanding literature
339 gaps, as well as cement illusions as valuable stimuli for the study of cognition.

Our findings suggest that the sensitivity to 10 different types of visual illusions share a common part of variance, supporting the existence of a general factor of illusion sensitivity (Factor *i*). This result comes in a field of mixed findings. In fact, contrary to early studies on visual illusions, more recent research have generally not found any significant evidence for a common stable factor across illusions within individuals^{12,15,16,20,50}. Instead, past findings suggest illusory effects are highly specific to the perceptual features of the illusions at stake^{15,20}. It should be noted, however, that most of these studies were low-powered and/or relied on conventional paradigms, such as the adjustment procedure to measure the participants' subjective perception. We believe that our study presents several methodological improvements, including statistical power (high number of trials per participant), homogeneous stimuli (with minimal and highly controlled features) and tasks (decision-making reaction-time task), and a more reliable participant-level score extraction method (based on random-factors models), which in our opinion contributed to the emergence of the common factor.

Finally, we found illusion sensitivity to be positively associated with "positive" personality traits, such as agreeableness and honesty-humility, and negatively associated with maladaptive traits such as antagonism, psychoticism, disinhibition, and negative affect. Although the existing evidence investigating links between illusion sensitivity and personality traits is scarce, these results are consistent with past findings relating pathological egocentric beliefs (often associated with psychoticism⁵¹) to reduced context integration, manifesting in a tendency to separate objects from their surroundings when processing visual stimuli^{19,51,52}. As such, the association between maladaptive traits and lower illusion sensitivity could be linked to a self-centered, decontextualized and disorganized information processing style. Conversely, the relationship between illusion sensitivity and adaptive personality traits is in line with the decreased field dependence (the tendency to rely on external cues in ambiguous contexts) associated with traits negatively correlated with agreeableness and honesty-humility, such as hostility, aggression

367 and narcissism^{18,19,53}.

368 Importantly, these findings highlight the relevance of illusions beyond the field of
369 visual perception, pointing towards an association with high-level domain-general
370 mechanisms. In particular, the evidence in favor of a relationship between maladaptive
371 personality traits and illusion sensitivity is in line with clinical observations, in which a
372 greater resistance to illusions have been reported among patients with schizophrenia^{7,16,53},
373 especially in association with schizotypal traits such as cognitive disorganization^{20,26}.
374 While the search for the exact mechanism(s) underlying these links is an important goal of
375 future research, our findings unlock the potential of illusion-based tasks as sensitive tools to
376 capture specific inter-individual neuro-cognitive differences.

377 Future research is needed to address several limitations. One key question concerns
378 the relationship of illusion sensitivity with perceptual abilities (e.g., using similar tasks, but
379 without illusions). Although the illusions used in the present study did differ in terms of
380 the perceptual task (contrast-based, size-estimation, angle-perception), the possibility of
381 our general factor being driven by inter-individual perceptual skills variability (or other
382 cognitive skills) cannot be discarded. Moreover, using only the error rate models to extract
383 individual-level scores might fail in capturing the whole range of behavioral dynamics.
384 Future work should attempt at integrating the reaction times data (e.g., by jointly
385 analyzing them using drift diffusion models), and assess the psychometric properties - such
386 as stability (e.g., test-retest reliability) and validity - of similar illusion-based paradigms.
387 Finally, while the personality measures used in this study highlight illusion sensitivity as an
388 interesting measure rather than a mere perceptual artifact, further studies should test its
389 relationship with more specific dispositional characteristics (e.g., autistic or schizotypal
390 traits), cognitive styles and abilities, to help understand the potential underlying
391 mechanisms of these associations.

392

Data Availability

393

The datasets generated and/or analysed during the current study are available in the

394

GitHub repository <https://github.com/RealityBending/IllusionGameValidation>

395

Funding

396

This work was supported by the Presidential Postdoctoral Fellowship Grant

397

(NTU-PPF-2020-10014) from Nanyang Technological University (awarded to DM).
